ABSTRACT: Raising the distance covered by singlet excitons during their lifetimes to values maximizing light absorption (a few hundred nm) would solve the exciton diffusion bottleneck issue and lift the constraint for fine (≈10 nm) phase segregation in bulk heterojunction organic solar cells. In that context, the recent report of highly ordered conjugated polymer nanofibers featuring singlet exciton diffusion length, $L_{DI}$, in excess of 300 nm is both appealing and intriguing [Jin, X.; et al. Science 2018, 360 (6391), 897−900]. Here, on the basis of nonadiabatic molecular dynamics simulations, we demonstrate that singlet exciton diffusion in poly(3-hexylthiophene) (P3HT) fibers is highly sensitive to the interplay between delocalization along the polymer chains and long-range interactions along the stacks. Remarkably, the diffusion coefficient is predicted to rocket by 3 orders of magnitude when going beyond nearest-neighbor intermolecular interactions in fibers of extended (30-mer) polymer chains and to be resilient to interchain energetic and positional disorders.

Singlet exciton diffusion is a ubiquitous process in organic electronics with important implications for light harvesting, namely, in photovoltaic applications. In the usually prevailing picture of disordered organic semiconductors, exciton transport is believed to occur via a sequence of thermally activated hopping events between individual molecules or polymer chains, ultimately holding back transport over large distances during the relatively short (~ns) singlet exciton lifetime. While the use of advanced synthetic methods has allowed the preparation of molecular and polymeric materials with a low degree of static, extrinsic, disorder, organic semiconductors are soft materials that suffer from dynamic (vibrational), intrinsic, disorder prompting spatial self-localization of the energy (and charge) carriers under the form of exciton-polarons (polarons). The recent report in highly organized conjugated nanostructures of exciton diffusion coefficients exceeding 1 cm$^2$/s, that is orders of magnitude larger than expectations based on incoherent hopping transport, is therefore an important breakthrough, but one that has remained elusive so far.

On the basis of a combined experimental-theoretical investigation, we proposed that the enhanced diffusivity along those P3HT one-dimensional stacks stems from a transient delocalization of the energy carriers. That is, the excitonic density of states (EDOS) in these fibers comprises states that spatially extend over a few polymer chains and are thermally accessible at room temperature from the localized states sitting at the bottom of the EDOS; these extended states can then be transiently populated during the exciton lifespan, kicking energy transport along the stacking direction. A similar mechanism has been proposed in the context of charge transport in molecular semiconductors. Here, we show that this transient delocalization mechanism is remarkably sensitive to the interplay between the amount of on-chain exciton delocalization and the spatial range of excitonic interactions along the fibers.

We start with an atomistic model of a supramolecular assembly of P3HT chains (schematic presentation is shown in Supporting Information Figure S1), each exactly 30 thiophene monomer units long, that mimics the fibers prepared by living crystallization self-assembly. We resort to a Frenkel–Holstein type mixed quantum-classical model including a multicentric transition density description of the Coulombic interchain excitonic interactions ($\tau_{x1}$) and accounting for the coupling to a leading high-frequency carbon–carbon stretching/breathing vibrational mode per chain ($\nu_{x1}$).

The measured absorption and emission spectral line shapes and line widths are reproduced by augmenting this model with effective low-frequency vibrations (\(\omega_k\)), mostly describing the conformational degrees of freedom along the polymer chains and including residual static disorder (\(\varepsilon_k\)); see below. \(\alpha_1\) and \(\alpha_2\) are the exciton–phonon coupling constants corresponding to the high- and low-frequency modes, and \(\langle k \rangle\) represents a local diabatic basis state of the stack where chain \(k\) is electronically excited while all other chains remain in their ground states. Meanwhile, the nuclear dynamics is determined by a classical Hamiltonian

\[
H_n = \sum_k \frac{1}{2} \left( m_{k,1} \dot{x}_{k,1}^2 + K_{x_{k,1}} x_{k,1}^2 + m_{k,2} \dot{x}_{k,2}^2 + K_{x_{k,2}} x_{k,2}^2 \right)
\]

\(\text{Figure 1. Influence of various disorders on singlet exciton diffusion coefficient along stacks of 30-mer P3HT polymer chains. Entries 1–3 are for static energetic disorder: } \sigma = 18 \text{ meV (entry 1), } 36 \text{ meV (entry 2), and } 72 \text{ meV (entry 3). Entries 4–7 are for paracrystalline disorder: } g_{\text{ex-x}} = 0\% \text{ (entry 4), } 1\% \text{ (entry 5), } 10\% \text{ (entry 6), and } 20\% \text{ (entry 7). Entries 8–10 are for dynamic disorder: } \sigma / \langle \tau^2 \rangle = 0 \text{ (entry 8), } 0.5 \text{ (entry 9), and } 1 \text{ (entry 10). D is found to be insensitive to the degrees of static energetic and positional disorders as modeled here, and increases slightly when accounting for dynamic nonlocal exciton–phonon interactions.}
\]

adiabatic molecular dynamics simulations on stacks of increasing cumulative positional disorder, with \(g_{\text{ex-x}}\) values ranging from 1% to 25%, where the variation in interchain distances modifies the long-range excitonic couplings. Much to our surprise, \(D\) remains almost unaffected (see Figure 1), within numerical error, by the degree of paracrystallinity, pointing to the fact that, irrespective of the mechanism at play, it is extremely resilient to static disorder.

The model discussed so far only includes local exciton–phonon interactions mimicking the formation of self-localized polaron–excitons on the polymer chains. For charge transport in the bandlike regime, it is notable that the nonlocal electron–phonon couplings, that is the variation of the intermolecular electronic interactions with distortions along the crystal phonons, tend to disrupt the translational symmetry, to confine the charge carriers in space and to plummet the room-temperature charge carrier mobility.6,7 In contrast, such off-diagonal dynamic disorder is beneficial to charge transport in the incoherent regime, where the hopping rates scale with the thermal average of the squared couplings, \(\langle \tau^2 \rangle\), the latter being augmented from the square of the nuclear-frozen mean values, \(\langle \tau^2 \rangle\), by the variance \(\sigma^2\) on thermal distribution.27 Here, we consider the conservative case of a fixed \(\langle \tau^2 \rangle\) and adjust \(\langle \sigma^2 / \langle \tau^2 \rangle \rangle\) so that the ratio \(\sigma^2 / \langle \tau^2 \rangle\) varies from zero to one, covering the full range of amplitude for the nonlocal exciton–phonon interactions (the modified Hamiltonian is shown in the methodology section of the Supporting Information). The results reported in Figure 1 show that larger dynamic fluctuations of the excitonic couplings result in a significant increase in \(D\) that reaches 0.65 cm²/s for \(\sigma^2 / \langle \tau^2 \rangle = 1\) (i.e., \(\langle \tau^2 \rangle = 0\)). Though this should be taken with a grain of salt in view of the approximations considered in the model, we note that including nonlocal exciton–phonon couplings brings the predicted diffusion coefficient closer to the value measured in highly organized P3HT nanofibers (and therefore away from the thin film results); a similar observation of the effect of...
nonlocal exciton–phonon coupling has been reported earlier in the study of exciton transport within molecular crystals.  

The origin for the large computed $D$ values turns out to be related to the excitonic interactions or, most specifically, their distance dependence. In this respect, we stress that the present study goes beyond previous studies, where only nearest-neighbor excitonic couplings were considered in the Hamiltonian.  

In the latter case (which would be very much representative for charge transport), the resulting diffusion coefficient drops to $\sim 6 \times 10^{-4}$ cm$^2$/s, that is about 3 orders of magnitude smaller than the value obtained when holding the full interaction range. Figure 2 portrays the evolution of the diffusion coefficient as the number of neighbors, and thus the range of excitonic couplings, increases (excitonic couplings beyond the fixed interaction range are excluded and set to zero in respective calculations). $D$ steadily grows with interaction range reaching only saturation when up to the first 15 neighbors are included, corresponding to interaction distances (15 times the intermolecular separation, $d_{ij}$) of $\sim 6$ nm. Interestingly, applying a nearest-neighbor model where excitonic interactions are renormalized to reproduce the full-range excitonic bandwidth (which boils down to multiplying the close contact excitonic couplings by a factor $\sim 3$) leads to a relatively modest increase in $D$ from $6 \times 10^{-4}$ cm$^2$/s to $5 \times 10^{-3}$ cm$^2$/s, revealing that what matters is the range of the interactions rather than their magnitude. The long-range nature of the excitonic interactions also makes the exciton diffusion process immune to dislocation defects in the stack, as shown in Supporting Information Figure S3, where the transient delocalization mechanism is still in play, even when $\sim 25\%$ of the chains in the stack are missing. Not surprisingly, the long-range dependence of $D$ directly follows from the Coulombic interactions and can be understood from a simple qualitative analysis. At interchain distances, $d_{ij}$, large with respect to the molecular size, $L$, these interactions can be reasonably well described using the point dipole approximation (PDA) and evolve as $L/d_{ij}^6$. At shorter distances, however, the PDA breaks down and largely overshoots the through-space Coulomb couplings. In fact, when expanding the molecular transition moments in the more accurate line dipole approximation (assigning for instance a local transition dipole to each monomer unit), it has been shown that the nearest excitonic interactions should decay inversely with molecular size, with scaling relationships ranging from $L^{-1}$ to $L^{-2}$ depending on the model used for on-chain delocalization. This reflects the destructive interferences between positive (H-like) and negative (J-like) local dipole–dipole interactions at short distances. Because this cancellation effect weakens as interchain separation increases (with the PDA becoming valid at very large $d_{ij}$), the excitonic couplings falloff slowly with distance, with the decay being best fit by a double exponential function; see Figure 3. We note that the Coulombic interactions used so far are based on gas-phase calculations; however, screening the long-range interactions to reproduce the Förster $1/n^2$ dependence, with $n^2 \sim \varepsilon$, here taken to be 4 for organics, only slightly reduces the diffusion coefficient (by less than 10%, see Supporting Information Figure S4).

A critical assessment on the role of long-range interactions can be grasped when considering the same P3HT nanofiber stacks, but now based on very short polymer chains (including 6 monomer units; see Supporting Information Figure S1). Indeed, shortening the interacting chromophores partly removes the destructive interactions between the monomer transition dipoles at close distance and should thus be accompanied by a faster falloff of the excitonic couplings, as indeed confirmed by quantum-chemical calculations, Figure 3. One consequence is that the first, nearest-neighbor, interactions are about six times larger in 6-mer compared to 30-mer aggregates, which translates into a slight increase in

---

**Figure 2.** Evolution of the singlet exciton diffusion coefficient with the spatial range of the excitonic interactions (interchain distance $d_{ij} = 3.85$ Å) for stacks comprising P3HT chains that are 30-mer long (orange circles) versus 6-mer long (blue triangles). The lines are guide to the eyes. In the 30-mer case, $D$ increases steadily over 3 orders of magnitude when an increasing number of neighbors are included in the simulations, reaching a plateau only after 16 neighbors ($\sim 6$ nm). A completely different behavior is predicted for the short (6-mer long) chains where the calculated diffusion coefficient is reduced by a factor $\sim 2$ when going from nearest-neighbor to full-range interactions.

**Figure 3.** Distance-dependent excitonic couplings in P3HT stacks of 30-mer long chains (orange circles) versus 6-mer long chains (blue triangles). To ease the comparison, the excitonic couplings have been renormalized (divided) by the nearest-neighbor values ($\sim 9$ meV in 30-mer stacks and $\sim 65$ meV in 6-mer stacks). The lines show fits of the data using the following double exponential functions: $r = 0.81 \times \exp(-0.99 \times d) + 0.5 \times \exp(-0.28 \times d)$ for 30-mer stack and $r = 1.80 \times \exp(-2.15 \times d) + 0.27 \times \exp(-0.68 \times d)$ for a 6-mer stack; $d$ is the separation between two polymer chains in the stack. Note that the falloff parameters are smaller in 6-mer versus 30-mer stacks.
interchain exciton delocalization (with thermalized (IPR) of ~1.3 in 6-mer versus ~1.1 in 30-mer). Yet, most remarkably, the diffusion coefficient obtained when retaining the full interaction range is about 1 order of magnitude smaller, with $D \sim 0.02 \text{ cm}^2/\text{s}$ in the 6-mer versus $0.2 \text{ cm}^2/\text{s}$ in the 30-mer one-dimensional stacks; see Figure 2. While being based on model systems, these results are representative of poorly ordered, solution-processed films of conjugated polymers featuring limited on-chain delocalization and conjugation length (here mimicked by using short physical lengths), for which the typical diffusion coefficients of $10^{-3} - 10^{-2} \text{ cm}^2/\text{s}$ translate into singlet exciton diffusion lengths in the 10 nm range. They, of course, also hold for small molecules. In both cases, in contrast with the situation prevailing for extended polymer chains, long-range interactions are found to be (slightly) detrimental to exciton diffusion, with $D$ values lowered by roughly a factor two when going from nearest-neighbor to full-range interactions (Figure 2). In the latter scenario, though the high-energy extended states are sporadically accessed, the exciton has higher probability to get trapped at the bottom of the EDOS (see Figure 4). As detailed above, this contrasting behavior in small versus extended chromophores originates from differences in the relative importance of long-range interactions. Because of the larger nearest-neighbor interactions and the ensued increased excitonic bandwidth, the number of spatially extended states transiently accessible at room temperature from the bottom of the excitonic DOS is reduced in the 6-mer (compared to the 30-mer) stacks; see representative trajectories in Supporting Information Figure S5. Including long-range interactions in the Hamiltonian for short polymer aggregates results in the formation of dynamic deep energy states (see Figure 4) that can act as trapping sites, explaining the decrease in $D$. The presence of these deep trap states in short polymer stacks is further supported by calculations including nonlocal exciton–phonon couplings, which demonstrates larger improvement in $D$ compared to that in long polymer stacks (see Supporting Information Figure S6), suggesting thermal fluctuations of excitonic couplings are essential in the case of short polymer aggregates to transiently access spatially extended states.

To summarize, we have conducted a comprehensive modeling study of singlet exciton diffusion in conjugated polymer nanostructures. Our calculations show that long-range interactions along the fibers prompt diffusion coefficients ($\sim 1 \text{ cm}^2/\text{s}$) conducive to the full usage of the singlet excitons photogenerated across the absorption light depth in organics. Such long-distance effects are characteristic features of conjugated polymers showing extended on-chain $\pi$-conjugation, as those prepared using living crystallization. In the spirit of ref 32, what matters to ensure long-range energy migration in these nanostructures relates more to the shape of the Hamiltonian than to the strength of the interactions. As a matter of fact, our excitonic Hamiltonian retaining the full range of interactions is intermediate between the nearest-neighbor one-dimensional model for charge transport and the star-like graph pertaining to polaritons, with the latter providing ensemble properties that are more robust to disorder than the former (i.e., more prompt to exciton delocalization thanks to reduced von Neumann entropy).32 Exciton delocalization along polymer chains somehow “redistributes” the total excitonic interactions among short- and long-range intermolecular contributions in a way that is favorable to energy migration between chains, the weak distance dependence of the excitonic interactions in the $\pi$-extended polymer chains offering multiple efficient pathways for long-distance energy migration. The resulting energy transport regime can be viewed as a generalized variable range hopping model that includes (transient) delocalization of the singlet excitons in the ordered nanostructures explored here.
